Preface

This report describes the soil-to-structure-to-limestone foundation interaction analysis used to assess potential wall performance of the new roller-compacted concrete north lock wall at McAlpine Locks. Funding for this study was provided by the U.S. Army Engineer District (USAED), Louisville. Mr. Larry Dalton and Ms. Monica Greenwell, Design Branch, USAED, Louisville, were the project monitors under the general supervision of Mr. Byron McClellan, Chief, Design Branch.

This work was performed at the U.S. Army Engineer Waterways Experiment Station (WES) by Dr. Robert M. Ebeling, Computer-Aided Engineering Division (CAED), Information Technology Laboratory (ITL), and by Mr. Ronald E. Wahl, Soil and Rock Mechanics Division, Soil Research Center, Geotechnical Laboratory. Mr. John Hendricks, ITL, provided invaluable assistance in processing the results of the computer analyses and preparing the figures for this report. The authors of this report are also indebted to Mr. Kevin Abraham, ITL, for rendering his timely assistance in the development of the finite element mesh of the lock. This report was prepared by Dr. Ebeling and Mr. Wahl. Review commentary was also provided by Mr. Dalton and Ms. Greenwell. The work was accomplished under the general direction of Mr. H. Wayne Jones, Chief, CAED, ITL, and Dr. N. Radhakrishnan, Director, ITL.

At the time of the publication of this report, Director of WES was Dr. Robert W. Whalin. Commander was COL Bruce K. Howard, EN.

Soil-Structure-Foundation Interaction Analysis of New Roller-Compacted Concrete North Lock Wall at McAlpine Locks

Background

A new lock is to be constructed at the McAlpine Locks on the Ohio River at Louisville, KY. The new lock chamber will be defined by rock-founded, gravity, earth-retaining monoliths. The design of these new lock walls was completed by Louisville and Portland District personnel. One of the alternatives is to construct the walls using roller-compacted concrete (RCC) with a concrete facing, with the culverts located in the floor of the lock chamber. The objective of this study was to assess the soil-to-structure-to-foundation interactions of a typical RCC lock wall two-dimensional (2-D) section.

This report describes the results of a complete soil-structure interaction (SSI) analysis of a typical section of the north wall of the new McAlpine Lock monolith using the backfill placement method of analysis incorporated in the finite element computer program SOILSTRUCT-ALPHA. SOILSTRUCT is used to understand the sometimes complex interactions among the lock, the backfill, and the foundation rock strata. The ALPHA version of SOILSTRUCT (Ebeling, Duncan, and Clough 1990) has been developed to analyze gravity lock walls like the McAlpine lock walls.

Section Analyzed

The north wall of the new RCC McAlpine Lock is shown in Figure 1. The lock wall being analyzed is 73 ft (22.25 m) high (above elevation 370[1]), 47 ft (14.33 m) wide and retains 55 ft (21 m) of well-compacted, dense granular back-fill. The base of the new lock (at el 370) is 9.5 ft (2.9 m) above the floor of the new lock chamber. The postconstruction water table in the backfill is assigned el 395, and the pool elevation is at el 383 in the complete SSI analysis. The section analyzed is representative of the north wall of the new lock at station 25+00. The complete 2-D section modeled in the analysis is shown in Figure 2. The section includes two of the existing lock walls, the existing backfill and shale foundation between these two locks, and a significant portion of the limestone foundation. The 2-D section was terminated at the center line of the existing McAlpine Lock and the center line of the new lock.

Backfill Placement Method of Analysis

One of the earliest successful applications of soil-structure interaction analysis was performed by Clough and Duncan (1969) in their analysis of the two reinforced-concrete U-frame locks at Port Allen and Old River. These two locks had been extensively instrumented. Prior to Clough and Duncan's analysis, the instrumentation data had been thought to be unreliable and contrary to the perceived understanding of the behavior of locks to loadings encountered during lock operation. Clough and Duncan's study showed that the best agreement between results computed using the finite element method and those obtained through instrumentation measurements is obtained when the actual construction process is simulated as closely as possible in the analysis. During their study, Clough and Duncan developed what is referred to as a *backfill placement analysis* in which the loads exerted by the backfill on the lock wall are generated automatically during simulated placement of backfill behind the wall (i.e., predetermined earth pressure force distributions between the soil and the lock are *not* specified). This requires that the soil backfill and foundation soil strata be included in the finite element mesh. This procedure involved the use of incremental finite element analysis with nonlinear, stress-dependent, stress-strain behavior for the soil. Linear elastic behavior was assumed for the concrete lock wall. An additional requirement is that interface elements be incorporated within the finite element mesh to allow for relative movement between the soil and structure. Since the Clough and Duncan study, soil-structure interaction analysis using the backfill placement procedure has been successfully applied to a variety of earth retaining structures. An extensive database of strength and hyperbolic stress-strain parameters (using data obtained from consolidated-drained triaxial tests on a variety of soils) has also evolved because of the extensive number of applications of this family of numerical procedures in engineering practice (see discussion in Ebeling and Mosher 1996). An updated version of SOILSTRUCT, referred to as SOILSTRUCT-ALPHA, is used in this study.

---

Soil-Structure-Foundation Interaction Analysis

Analysis Description

SOILSTRUCT-ALPHA (Ebeling, Duncan, and Clough 1990) is a special-purpose, finite element program for 2-D, plane strain analysis of soil-structure interaction problems. SOILSTRUCT calculates displacements and stresses resulting from incremental construction, backfilling, excavation, dewatering, rising water table, and/or load application. Nonlinear, stress-path-dependent, stress-strain behavior of the backfill was approximated in the finite element analysis using the tangent modulus method. In the tangent modulus method, new values of tangent moduli are assigned to each soil element at each increment of loading (i.e., dewatering, lock construction, and backfilling) or unloading (i.e., excavation, rising water table). The modulus values assigned to each element are adjusted in accordance with their stresses to simulate nonlinear behavior.

SOILSTRUCT was expanded during the U.S. Corps of Engineers' first Repair, Evaluation, Maintenance, and Rehabilitation (REMR) Research Program to model the loss of contact between the base of a wall (a lock in this case) and its rock foundation using a procedure called the ALPHA method (Ebeling, Duncan, and Clough 1990; Ebeling et al. 1992). The ALPHA method was extended to soil elements by Regalado, Duncan, and Clough (1992) to reduce numerical inaccuracies in soil elements that are at or near failure.

Another enhancement contained within this version of SOILSTRUCT is the reintroduction of the hyperbolic shear-stress displacement relationship for the interface element. Although present in the original version of SOILSTRUCT (Clough and Duncan 1969), this nonlinear relationship was missing from the version of computer code in which the alpha method was incorporated.

The continua elements used to model the soil and the soil-to-structure interface elements which may have failed in shear at one stage of loading have the ability to recover their shear stiffness and shearing resistance as a result of an increase in confining pressures at some later stage of loading in this version of SOILSTRUCT-ALPHA. Several other improvements have been made to the material models and to the numerical procedures implemented within SOILSTRUCT-ALPHA based on experience gained at the U.S. Army Engineer Waterways Experiment Station (WES) in conducting SSI analyses of different types of Corps structures.

In summary, the ALPHA version of SOILSTRUCT used on this project contains numerous improvements to the analytical procedures used for modeling various aspects of features impacting the SSI of lock walls. Several of these features are deemed by the authors of this report to be critical to an accurate assessment of the SSI of the north wall section of the new McAlpine Lock.

Soil-Structure-Foundation Interaction Analysis of New McAlpine Lock North Wall Section

Lock construction, backfilling, and submergence model

Project engineers at the Louisville District established that the probable scheduling of construction of the new lock is placement of a 1.5-ft- (0.46-m-) thick layer of RCC followed by placement of backfill to the top of the newly placed RCC lift. Each layer of RCC possesses sufficient stiffness at the time of placement to support construction equipment. This staged (incremental) construction proceeds until the final elevations (Figure 3) are reached on the new lock and backfill. Incremental construction of the RCC and placement of the backfill behind the wall is staggered by one lift in the SOILSTRUCT-ALPHA incremental construction/backfill placement analysis. This altered construction schedule in the analysis results in a "stiffer" layer of RCC elements being in place, adjacent to the newly placed layer of soil. Thus, the conditions in the field are modeled in the finite element analysis. The stages of loading used in the SOILSTRUCT-ALPHA analysis are described in the following paragraphs.

The complete SSI of the north wall of the new McAlpine Lock cross section (Figure 2) is modeled in three phases. The first phase of the analysis introduces the self-weight of the existing locks and existing backfill to the shale and limestone foundation. This is accomplished using the gravity turn-on option in SOILSTRUCT-ALPHA prior to construction of the new lock and placement of new backfill. This initial phase is illustrated in Figure 4a for load case "I." The second phase models the incremental construction of the RCC lock wall and the incremental placement of the (moist) backfill behind the wall. The third phase of the SSI analysis models the postconstruction, partial submergence of the site. Table 1 lists the initial stage of loading and each of the subsequent 38 stages of loading in the SSI analysis of the north wall section of the new McAlpine Lock.

The incremental construction of the RCC lock wall is modeled in the first 24 load cases (following the gravity turn-on analysis), with the incremental placement of the moist backfill during 22 of these load increments. Figure 3 shows the thickness of the layers of RCC and backfill that are used in this second phase of the analysis. The thickness of the layers range from 1.5 ft (0.46 m) thick at the bottom to 5 ft (1.5 m) thick at the top. Placement of the first 1.5-ft- (0.46-m) thick layer of RCC of the new lock wall precedes the placement of the first layer of backfill in the SOILSTRUCT-ALPHA analysis, labeled load case 1 in Table 1 and in Figure 4a. This allows the first layer of RCC to "stiffen" prior to the placement of the adjacent backfill layer in the analysis. The second load case models placement of the first 1.5-ft-thick layer of moist backfill, labeled load case 2 in Table 1 and shown in Figure 4a. The second, "soft" 1.5-ft- (0.46-m) thick layer of RCC is also placed to el 373 in load case 2 to expedite the analysis (and without compromising accuracy). Incremental construction of the next layer of "softer" RCC layer precedes the placement of the next layer of backfill by one

(Sheet 3 of 3)

lift throughout the analysis (as shown in Figures 4a and 4b, and Table 1). This allows SOILSTRUCT-ALPHA to account for the stiffer RCC immediately adjacent to the newly placed layer of backfill. Incremental placement of the backfill to el 425 concludes with load case 23, and incremental construction of the lock concludes with load case 24 (Figure 4b).

The third phase of SSI analysis models the postconstruction, partial submergence of the site and is accomplished using SOILSTRUCT-ALPHA in 14 load cases. The water table in the existing and new lock chambers is raised incrementally to el 383, and the water table in the new backfill is raised incrementally to el 395 (listed as load cases 25 through 38 in Table 1). A hydrostatic water table is assumed for the backfill in all load cases. Loadings consist of buoyancy forces acting within the newly placed backfill and boundary water pressures acting normal to both faces and base of the new RCC lock, the limestone foundation, and the faces of the two existing lock walls. A linear (uplift) pore water pressure distribution is applied along the new RCC lock-to-limestone foundation interface, with the uplift (pressure) heads set equal to 13 ft (3.96 m) below the toe and 25 ft (7.6 m) below the heel of the wall.

Figure 4c shows the incremental submergence of the backfill for load cases 25 and 26 and for the final load case of 38. The partial submergence of the site is accomplished in the finite element model using two features in SOILSTRUCT-ALPHA: application of buoyancy forces to the submerged backfill and application of boundary water pressures along the faces of impermeable materials (i.e., all locks and the foundation). The buoyancy loads acting on the submerged soil elements are applied using the SEEP option in SOILSTRUCT. This subroutine is modified for this analysis to account for the difference between the submerged and moist unit weights for the soil. The water table is raised in the newly placed backfill in the last 14 load increments (Table 1). Water pressures acting normal to both faces and base of the new RCC lock, the limestone foundation, and the faces of the two existing lock walls are applied incrementally in load cases 32, 35, and 38, as shown in Figure 5. The interface elements used to model the RCC lock-to-limestone interface allow for the application of pore water pressures directed upward along the base of the new RCC lock and boundary water pressures directed downward along the top face of the limestone interface region. This distribution of pore water pressure corresponds to the nonsite-specific uplift pressure distributions recommended for the design of new locks (Headquarters, Department of the Army 1995) and is consistent with steady-state confined flow along a joint of constant aperture (Ebeling and Pace 1996, 1997).

Finite element mesh

Figure 6 shows the finite element mesh of the Figure 2 cross section of the north wall of the new lock. The mesh comprises 3,784 nodal points and 3,634 continua and 162 interface elements. Of the 3,634 continua elements, 468 model new RCC lock and concrete facing, 2,154 model the limestone and shale foundation, and 550 model the new backfill. The remaining 462 continua
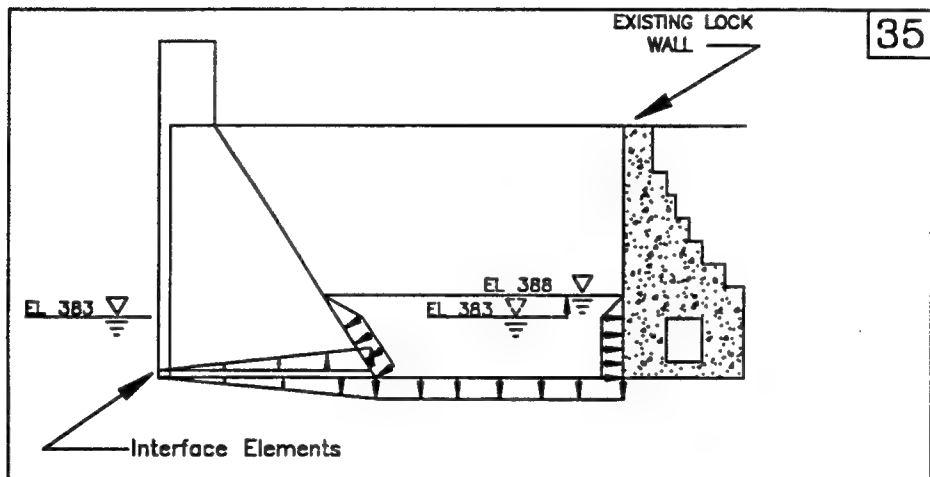

Figure 5. Incremental boundary water pressures applied in three load cases
(0.305 m = 1 ft)

Figure 6. Finite element mesh of north wall section of new RCC McAlpine Lock (0.305 m = 1 ft)

elements represent the two existing locks and the existing backfill between these locks. Of the 162 interface elements, 30 model the new RCC lock-to-limestone foundation interface, 25 model the limestone-to-new backfill interface, 22 model the new RCC lock-to-new backfill interface, and 22 model the existing lock-to-new backfill interface. Forty-six of the remaining interface elements are in the limestone foundation along two vertical planes, each extending through the limestone foundation from the heel of the new RCC lock wall and from the existing lock wall, respectively. These 46 interface elements are "locked" together with the assignment of high normal and shear stiffnesses. The remaining 17 interface elements extend along el 370 from the front face of the existing center lock wall, to the culvert of the existing, operational lock wall and are locked together with high normal and shear stiffnesses.

Material properties

Table 2 lists the values assigned to the elastic parameters of the RCC, the concrete facing for the new lock, the concrete of the existing locks, and the limestone and shale foundation. The elastic parameters assigned to the RCC are based upon data obtained for the RCC mixture used on the Willow Creek Dam project and provided by Portland District personnel. The soil that comprises the backfill for the new RCC lock will be a well-compacted, well-graded, dense granular backfill. Moist and saturated unit weights equal 126 pcf (2,018.33 kg/m^3) and 130 pcf (2,082.39 kg/m^3), respectively. Site-specific triaxial test data are unavailable for the backfill. Material parameters are assigned in the finite element analysis based on empirical correlations to the results for similar types of soils (and with the same density) for which hyperbolic stress-strain curve material parameters are available (e.g., Duncan et al. 1978). An additional requirement for the soil model was that the assigned soil properties correspond to an at-rest earth pressure coefficient K_o equal to 0.44, based on the Jaky equation for K_o [$=1 - \sin \phi'$] with ϕ' equal to 34 deg. Appendix A describes the calculations made that result in the assignment of values for the hyperbolic stress-strain soil model of the backfill given in Table 3. These calculations include a settlement analysis made using SOILSTRUCT-ALPHA of a 55-ft-(16.76-m) high, one-dimensional (1-D) soil column due to self-weight of the moist soil.

Similarly, no specific tests are performed to define the hyperbolic shear stress-relative displacement relationship for the interface element used in SOILSTRUCT-ALPHA. The assignment of material parameters to the interface elements are based on empirical correlations to interfaces having similar types of soils (and with the same density) for which hyperbolic stress-strain curve material parameters are available (e.g., Clough and Duncan 1969, and Peterson et al. 1976). Table 4 summarizes the interface model and strength parameters assigned to the RCC lock-to-limestone foundation. Zero tensile strength is assumed for the material comprising the RCC lock-to-limestone foundation interface in this analysis. Table 5 summarizes the material properties assigned to the interfaces between the RCC-to-backfill, the limestone-to-backfill, and the existing lock wall concrete-to-backfill regions.

Table 2
Elastic Material Properties for 2-D Elements Comprising
SOILSTRUCT-ALPHA Finite Element Model of New RCC McAlpine
Lock (0.517 kN/m^3 = 1 pcf, 6.894 psi = 1 kPa)

Material Type	Unit Weight, pcf	E, psi	v
RCC	150	2,000,000	0.21
Concrete Face	145	3,400,000	0.15
Existing Concrete	145	3,400,000	0.15
Limestone	--	5,000,000	0.25
Shale	--	3,000,000	0.25

During the postconstruction partial submergence of the backfill to el 395 (identified as load cases 25 through 38 in Table 1), the buoyancy forces act upward, unloading the backfill. This results in a reversal in the direction of the applied shear stress increment or, equivalently, unloading of both the new RCC lock-to-backfill interface elements and the existing lock concrete-to-backfill interface elements. Interface tests reported in Peterson et al. (1976) show that the interface elements follow a steeper shear stress versus relative shear displacement curve than that described by the "primary" hyperbolic loading curve (the tangent shear stiffness $k_{st} = k_{si}[1 - R_{fi}SL]^2$). To model this behavior, the interface model parameter R_{fi} is set equal to zero for these interface elements during unloading. This eliminates the "shear softening" while maintaining the influence of the effective normal stress on the value of the tangent shear stiffness k_{st} by means of the term k_{si} (Table 4). This concept is discussed further in Appendix B.

Results of Soil-Structure-Foundation Interaction Analysis of New McAlpine Lock North Wall Section

Following the gravity turn-on analysis, the incremental construction of the RCC lock wall and placement of moist backfill is modeled in the first 24 load cases for the finite element model of the McAlpine lock shown in Figure 6. This is followed by the postconstruction, partial submergence of the site in 14 load cases. The results of this complete SSI analysis follow.

Effective normal and shear stress distributions computed at base of new lock wall

Figures 7 and 8 show the resulting effective normal and shear stress distributions along the RCC lock-to-limestone interface after construction of the new lock and backfilling to el 425 (load case 24). Both effective normal and shear

Equations for Interface Model

The normal stress at the center of the interface element is given by

$\sigma_n = k_n \Delta_n$

where Δ_n is the average relative displacement normal to the interface element. The shear stress at the center of the interface element is given by

$\tau_s = k_s \Delta_s$

where Δ_s is the average relative shear displacement along the interface element.

---

effective normal stress below the heel of the new RCC lock (x = 47 ft) is equal to 1,626 psf (7,939 kg/m²). Flooding of the lock chamber to el 383 and partial submergence of the backfill to el 395 (load case 38) reduce the effective normal stresses and increase the shear stresses along the base, as shown in Figures 7 and 8. The effective normal stress below the heel of the new RCC lock is reduced to 0 psf (kg/m²); however, full base area contact is maintained.

Results after backfilling to el 425

Figures 9 and 10 show the variation of horizontal effective stress σ'_x and shear stress τ_{xy} with elevation along a vertical plane extending through the backfill from the heel of the new RCC lock wall (x = 47 ft (14.33 m)) after backfilling to el 425 (load case 24 in Table 1). This section is designated as section A-A (see Figure 11) throughout this report. As anticipated, these figures show the resulting effective horizontal and shear stress distributions to increase with depth below the surface of the backfill.

The resultant horizontal effective force of the Figure 9 distribution of σ'_x, F_x, is equal to 83,367 lb per ft run of wall (1,216.7 kN per m) and acts at el 390.28 (= $0.37 H_{backfill}$) along section A-A. The horizontal earth pressure coefficient K_h is computed along section A-A using the relationship

$$K_h = \frac{F_x'}{Effective\ Overburden} \tag{1}$$

Concrete-to-Backfill	34	1.0×10^4	0.8	0.9	1.0×10^8
Limestone-to-Backfill	34	1.0×10^4	0.8	0.9	1.0×10^8

Equations for the Interface Model

The normal stress at the center of the interface element is given by

$$\sigma_n = k_n \, \Delta_n$$

where Δ_n is the average relative displacement normal to the interface element. For each load increment, the change in shear stress at the center of the interface element is given by

$$\Delta \tau_s = k_{st} \, \Delta_s$$

where Δ_s is the average change relative shear displacement along the interface element.

$$k_{st} = k_{si} \, (1 - R_{fi} \, SL_i)^2$$

$$k_{si} = K_j \, \gamma_w \left(\frac{\sigma'_n}{P_a} \right)^{n_j}$$

$$SL_i = \tau / \tau_{Failure} = \tau / (\sigma'_n \tan \phi_i)$$

γ_w = unit weight of water P_A = atmospheric pressure

where the Effective Overburden is defined as

$$\text{Effective Overburden} = \int_{El\ 370}^{El\ 425} \sigma'_{overburden} \, dy \qquad (2)$$

In the case of a 55-ft- (16.76-m) high column of moist backfill with γ_{moist} equal to 126 pcf (2,018.3 kg/m^3), Equation 2 for the Effective Overburden becomes

$$\text{Effective Overburden} = \frac{1}{2} \, \gamma_{moist} \, (H)^2 \qquad (3)$$
Figure 7. Effective normal stress distributions along the base of new RCC lock wall (0.305 m = 1 ft, 47.88 Pa = 1 psf)

and is equal to 190,575 lb per ft run of wall (2,781.2 kN per m). The value for K_h after backfilling to el 425 is equal to 0.437 by Equation 1.

Calculation of the resultant horizontal effective force F_x of the resulting distributions of σ'_x with elevation in the backfill is made after backfilling to el 425 for two other vertical sections. Figure 11 shows the locations of the three sections used in the summary of the results. The two additional sections are designated as section B-B at x = 74.5 ft (22.7 m), and section C-C at x = 100.9 ft (30.75 m). Table 6 summarizes the results of calculations made to determine the

22
Figure 8. Shear stress distributions along the base of new RCC lock wall (0.305 m = 1 ft, 47.88 Pa = 1 psf)

resultant horizontal effective force F_x and horizontal earth pressure coefficient K_h at sections A-A, B-B, and C-C. The table shows the resultant horizontal effective force F_x for these two distributions of σ'_x (not shown) result in values of F_x equal to 83,520 lb per ft run of wall (1,218.9 kN per m) (section B-B) and 71,198 lb per ft run of wall (1,039.1 kN per m) (section C-C). Figure 11 also shows the variation in horizontal earth pressure coefficient K_h, within distance from the back of the new RCC lock wall for the three sections. Figure 11 shows the values for K_h equals 0.437 adjacent to the new RCC lock wall (section A-A, 0.438 at section B-B, and 0.374 adjacent to the existing lock wall (section C-C).
Figure 9. Horizontal effective stress distributions along section A-A after backfilling to el 425 (0.305 m = 1 ft, 47.88 Pa = 1 psf)

Note that the values for K_h at sections A-A and B-B are just slightly less than 0.44, the value for K_o from the 1-D soil column settlement analysis reported in Appendix A. Recall that the conditions corresponding to a K_o stress state within the soil exist in a region of constrained, uniform settlement. The value of K_h at section C-C is 18 percent less than the K_o value because of the influence of the large vertical shear force acting along this plane (to be discussed subsequently) resulting from the presence of the existing concrete lock wall at x = 102 ft (31.09 m).

The resultant vertical shear force of the Figure 10 distribution of τ_{xy}, F_v, is equal to 11,416 lb per ft run of wall (166.6 kN per m) along section A-A. The

24
Figure 10. Shear stress distributions along section A-A after backfilling to el 425 (0.305 m = 1 ft, 47.88 Pa = psf)

vertical earth pressure coefficient K_v is computed along section A-A using the relationship

$$K_v = \frac{F_v}{Effective\ Overburden} \tag{4}$$

where the Effective Overburden is equal to 190,575 lb per ft run of wall (2,781.2 kN per m) by Equation 3. The value for K_v after backfilling to el 425 is equal to 0.06 by Equation 4.
Figure 11. Variation of horizontal earth pressure coefficient, K_h, with distance from heel of new RCC lock wall after backfilling to el 425 (0.305 m = 1 ft)

Table 6
Summary of SOILSTRUCT-ALPHA Results After Backfilling New RCC McAlpine Lock to el 425 (14.594 N per m = 1 lb per ft run of wall)

Section	Effective Overburden, lb per ft run of wall	F_x', lb per ft run of wall	F_v, lb per ft run of wall	K_h	K_v
A-A	190,575	83,367	11,416	0.437	0.060
B-B	190,575	83,520	-4,990	0.438	-0.026
C-C	190,575	71,198	-34,869	0.374	-0.183

Calculation of the resultant vertical shear force F_v from the resulting distributions of τ_{xy} with elevation is made after backfilling to el 425 for sections B-B and C-C. Table 6 summarizes the results of calculations made to determine the resultant vertical shear force F_v and vertical earth pressure coefficient K_v at sections A-A, B-B, and C-C. The table shows that the resultant vertical shear force, F_v, for these two distributions of τ_{xy} (not shown) result in values of F_v equal to 4,990 lb per ft run of wall (72.8 kN per m) (section B-B) and 34,869 lb per ft run of wall (508.9 kN per m) (section C-C). Figure 12 shows the variation in vertical earth pressure coefficient K_v, within distance from the back of the new RCC lock wall for the three sections. Figure 12 shows the values for K_v equal 0.06 adjacent to the new RCC lock wall (section A-A), 0.026 at section B-B, and 0.183 adjacent to the existing lock wall (section C-C). The values for K_v for sections B-B and C-C are plotted as negative values to note that the corresponding vertical shear forces at these sections act counter to the direction of F_v along section A-A, as shown in the three diagrams in Figure 12. Note that had there been no differential settlement across a vertical section in the backfill, F_v and K_v would be equal to 0. (This is the case for the settlement of the Appendix A 1-D soil column due to self-weight.) F_v and K_v are nonzero at the three sections because of the close proximity of the two shear faces furnished by the new RCC lock and the existing lock walls.

Table 7 summarizes the resultant forces and their points of application on the free body of the new RCC lock wall shown in Figure 13 after backfilling to el 425. These resultant forces and their points of application are computed by SOILSTRUCT-ALPHA using the distributions of effective normal and shear stresses computed within the interface elements located along the back of the new RCC lock wall and along the base of the lock wall for load case 24. Twenty-two interface elements delineate the back of the RCC lock wall, and thirty interface elements delineate the base of the lock wall. The Table 7 values of forces and their points of application are consistent with the actual distribution of stresses along the two planes defined by the two groups of interface elements because of the analytical formulation used to define the interface elements in SOILSTRUCT-ALPHA. The Table 7 results show that the amount of shear (or "downdrag") along the back of the new RCC lock wall is significant and corresponding to a mobilized angle of interface friction δ_{mob} equal to 25.28 deg.

$$F_v = K_v \cdot \text{(Effective Overburden)}$$

Results after partial submergence to el 395

Figures 14 and 15 show the variation of horizontal effective stress σ'_x and shear stress τ_{xy} with elevation along section A-A after backfilling to el 425 and after partial submergence of the backfill to el 395 (load cases 24 and 38, respectively). As anticipated, these figures show that the resulting effective horizontal and shear stress distributions increase with depth below the surface of the backfill. Figure 14 shows that the magnitude of the values of σ'_x below el 395 decreases with the partial submergence of the site. Figure 15 shows that the magnitude of the values of τ_{xy} decreases with the partial submergence of the site. During postconstruction, after partial submergence of the backfill to el 395, the buoyancy forces act upward, thereby unloading the backfill. This also results in a reversal in shear stress increment.

The resultant horizontal effective force of the Figure 14 distribution of σ'_x, F'_x, is equal to 79,102 lb per ft run of wall (1,154.4 kN per m) and acts at el 390.99 ($= 0.38H_{backfill}$) along section A-A after partial submergence of the backfill to el 395. The horizontal earth pressure coefficient K_h is computed along section A-A using Equation 1, with the Effective Overburden computed using Equation 2. In the case of partially submerged, 55-ft- (16.76-m-) high column [with γ_{moist} equal to 126 pcf (2,018.32 kg/m^3) and $\gamma_{saturated}$ equal to 130 pcf (2,082.39 kg/m^3)], Equation 2 for the Effective Overburden becomes

$$= \left[\frac{1}{2} \gamma_{moist} (D_1)^2 + \gamma_{moist} (D_1 D_2) + \frac{1}{2} \gamma_{buy} (D_2)^2 \right] \tag{5}$$

where

D_1 = the thickness of backfill above the hydrostatic water table = 30 ft (9 m)

D_2 = the thickness of submerged backfill above the base of the wall = 25 ft (7.6 m)
Figure 13. Planes along surfaces of the new RCC lock on which resultant forces are computed after backfill is placed to el 425 (0.305 m = 1 ft)

γ_{buy} = buoyant unit weight of submerged backfill, $\gamma_{saturated}$ - γ_w

γ_w = unit weight of water = 62.4 pcf (999.55 kg/m^3)

and is equal to 172,325 lb per ft run of wall (2,514.9 kN per m). The value for K_h after partial submergence of the backfill to el 395 is equal to 0.459 by Equation 1.

Calculation of the resultant horizontal effective force F_x of the resulting distributions of σ'_x with elevation in the backfill is made after partial sub-mergence of the backfill to el 395 for sections B-B and C-C. Table 8 summarizes the results of calculations made to determine the resultant horizontal effective force F_x and horizontal earth pressure coefficient K_h at sections A-A, B-B, and
Figure 14. Horizontal effective stress distributions along section A-A (0.305 m = 1 ft, 47.88 Pa = 1 psf)

C-C. The table shows the resultant horizontal effective force F_x for these two distributions of σ'_x (not shown) result in values of F_x equal to 79,022 lb per ft run of wall (1,153.2 kN per m) (section B-B) and 68,475 lb per ft run of wall (999.3 kN per m) (section C-C). Figure 16 shows the variation in horizontal earth pressure coefficient K_h , with distance from the back of the new RCC lock wall for the three sections. Figure 16 shows the values for K_h equals 0.459 adjacent to the new RCC lock wall (section A-A), 0.459 at section B-B, and 0.397 adjacent to the existing lock wall (section C-C). The values for K_h after partial submergence of the backfill to el 395 (Figure 16) are greater than the values for K_h after backfilling to el 425 (Figure 11) as a result of the "unloading" of the soil during submergence.

Txy (psf)
Figure 15.   Shear stress distributions along section A-A (0.305 m = 1 ft, 47.88 Pa = 1 psf)

The resultant vertical shear force of the Figure 15 distribution of τ_{xy}, F_v, is equal to 6,775 lb per ft run of wall (98.9 kN per m) along section A-A. The vertical earth pressure coefficient K_v is computed along section A-A using Equation 4 with the Effective Overburden equal to 172,325 lb per ft run of wall (2,514.9 kN per m) by Equation 5. The value for K_v after partial submergence of the backfill to el 395 is equal to 0.039 by Equation 4.

Calculation of the resultant vertical shear force F_v of the resulting distribu-tions of τ_{xy} with elevation in the backfill is made after partial submergence of the backfill to el 395 for sections B-B (x = 74.5 ft (22.7 m)) and section C-C (x =

Table 8					
Summary of SOILSTRUCT-ALPHA Results After Backfilling New RCC McAlpine Lock to El 425 and After Submergence to El 395 (14.594 N per m = 1 lb per ft run of wall)					
Section	Effective Overburden, lb per ft run of wall	F_x', lb per ft run of wall	F_v, lb per ft run of wall	K_h	K_v
A-A	172,325	79,102	6,775	0.459	0.039
B-B	172,325	79,022	-4,241	0.459	-0.025
C-C	172,325	68,475	-25,389	0.397	-0.147

100.9 ft (30.75 m)), with the results summarized in Table 8. The table shows the resultant vertical shear force F_v for these two distributions of τ_{xy} (not shown) result in values of F_v equal to 4,241 (section B-B) and 25,389 (section C-C). Figure 17 shows the variation in vertical earth pressure coefficient K_v, within distance from the back of the new RCC lock wall for the three sections. Figure 17 shows the values for K_v equal 0.039 adjacent to the new RCC lock wall (section A-A), 0.025 at section B-B, and 0.147 adjacent to the existing lock wall (section C-C). The values for K_v after partial submergence of the backfill to el 395 (Figure 17) are less than the values for K_v after backfilling to el 425 (Figure 12). This behavior is a result of the buoyancy forces acting upward, thereby unloading the backfill and reversing the direction of the applied shear stresses (as compared to their direction during backfilling) along the faces of the new RCC and existing lock walls.

Table 9 summarizes the resultant forces and their points of application on the free body of the new RCC lock wall through which imaginary section(s) (shown in Figure 18) are made. These resultant forces and their points of application are computed by SOILSTRUCT-ALPHA after backfilling to el 425 (load case 24 in Table 1) and after partial submergence of the backfill to el 395 (load case 38). The Table 9 results show that the shear force F_s along the back of the new RCC lock wall is reduced by 16.6 percent with submergence of the backfill to el 395 as compared to the results in Table 7 (load case 24). The mobilized angle of interface friction δ_{mob} is reduced from 25.28 to 23.33 deg with partial submergence of the backfill.

Summary

This report summarizes the results of a complete soil-structure interaction analysis of the new RCC McAlpine Lock using SOILSTRUCT-ALPHA. The principal results are as follows:

a. A complete soil-structure interaction analysis of the new RCC McAlpine Lock results in nonlinear effective normal and shear stress distributions

Figure 16. Variation of horizontal earth pressure coefficient, K_h, with distance from heel of new RCC lock wall after submergence to el 395 (0.305 m = 1 ft)

$$F_v = K_v \bullet \text{(Effective Overburden)}$$

* Negative values of K_v reflect F_v directed upward on sections B — B and C — C
Figure 17. Variation of vertical earth pressure coefficient, K_v, with distance from heel of new RCC lock wall after submergence to el 395 (0.305 m = 1 ft)

Table 9
Summary of SOILSTRUCT-ALPHA Results After Backfilling New RCC McAlpine Lock to El 425 and After Submergence to El 395 (14.594 N per m = 1 lb per ft run of wall, 0.305 m = 1 ft)

For Load Cases 24 and 38									
Load Case	F_a, lb per ft run of wall	F'_n, lb per ft run of wall	I_{Fn}/ft	I_{Fn}/L	δ_{mob}, deg	T, lb per ft run of wall	N', lb per ft run of wall	x_N, ft	x_N/B
24	66,435	140,661	21.96	0.34	25.28	83,003	405,573	17.98	0.38
38	55,404	128,436	23.32	0.36	23.33	93,820	347,902	16.18	0.34

For Load Case 38							
Load Case	U_{base}, lb per ft run of wall	x_{Ubase}, ft	$\dfrac{x_{Ubase}}{B}$	U_{front}, lb per ft run of wall	h_{Ufront}, ft	U_{back}, lb per ft run of wall	I_{Uback}, ft
38	66,435	25.97	0.55	5,272.8	4.33	23,113	9.88

where B = 47 ft, L = 65.19 ft, and $\tan(\delta_{mob}) = \dfrac{F_s}{F'_n}$

along the base of the lock at the end of backfilling to el 425, and after flooding the lock to el 383 and partial submergence of the backfill to el 395.

b. Full base contact is maintained throughout all (38) stages of loading. However, the effective normal stress below the heel of the new RCC lock is reduced to 0 (kPa) psf after flooding the lock to el 383 and partial submergence of the backfill to el 395.

c. Among the results computed in a backfill placement analysis is the distribution of horizontal effective stress at three vertical sections in the backfill. At section A-A, the value of the effective horizontal force F_x is computed from the distribution of effective horizontal stress σ'_x along a vertical plane extending through the backfill from the heel of the wall. The value for F_x is also characterized in terms of the value of the horizontal earth pressure coefficient K_h. The results of the SSI analysis shows that F_x decreases as a result of the submergence of the backfill and the value of K_h increases.

d. The value of K_h at section C-C is less than the values of K_h at sections A-A and B-B because of the influence of the large vertical shear force
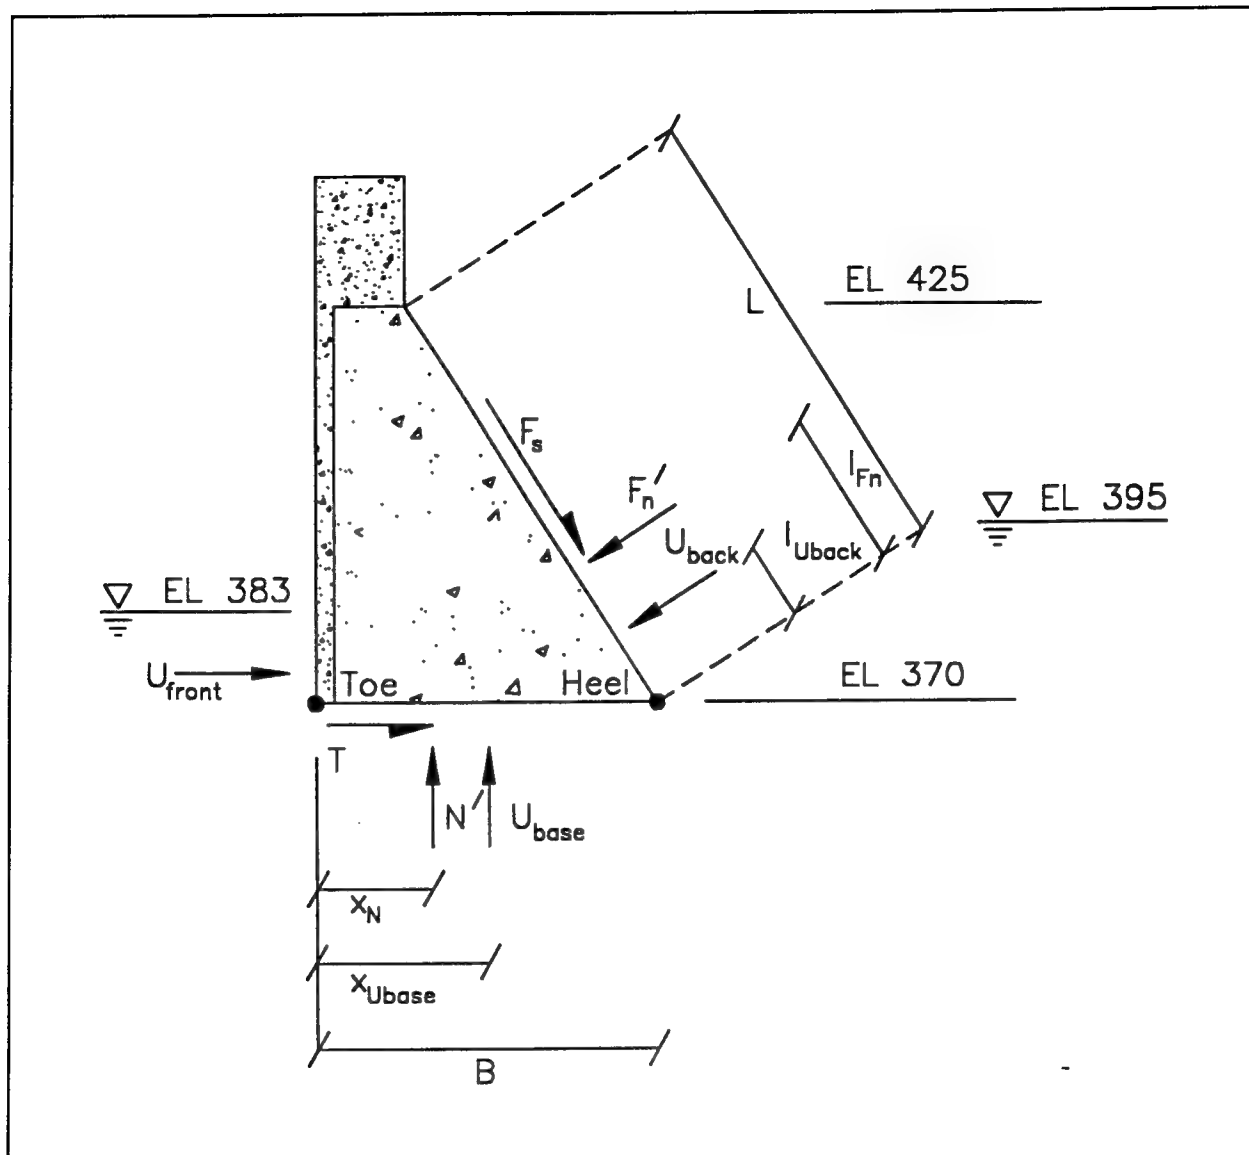

Figure 18. Planes along surfaces of the new RCC lock on which resultant forces are computed - submergence to el 395 (0.305 m = 1 ft)

along this plane, caused by the presence of the existing lock wall. Recall that section C-C is immediately adjacent to the existing lock wall.

e. The distribution of shear stress at three vertical sections in the backfill is also computed in a backfill placement analysis. At section A-A, the value of the vertical shear force F_v is computed from the distribution of shear stress τ_{xy} along a vertical plane extending through the backfill from the heel of the wall. The value for F_v is also characterized in terms of the value of the vertical earth pressure coefficient K_v. The results of the SSI analysis shows that F_v, or, equivalently, K_v, reduces as a result of the submergence of the backfill.

f. This SSI analysis shows that in the case of a postconstruction rise in the groundwater level in the backfill, a rebound of the soil occurs. This results in a reduction in effective stress in the backfill and a reduction in the shear force F_v. This also occurred at Red River Lock No. 1 (Ebeling et al. 1993, or Ebeling and Mosher 1996).

g. During the postconstruction, partial submergence of the backfill to el 395, the buoyancy forces act upward, unloading the backfill. This results in a reversal in the direction of the applied shear stress increment or, equivalently, unloading of both the new RCC lock-to-backfill interface elements and the existing lock concrete-to-backfill interface elements. Interface tests reported in Peterson et al. (1976) show that the interface elements follow a steeper shear stress versus relative shear displacement curve than that described by the "primary" hyperbolic loading curve. Incorporating this type of interface behavior in the SSI analysis of the new RCC McAlpine Lock wall is important to the accuracy of the computed results.

h. Appendix B reports on the errors related to using the "softer" primary hyperbolic curve for the interface elements during partial submergence of the backfill to el 395 compared to the results from using the more appropriate "stiffer" shear stress versus relative shear displacement curve. The most important error resulting from using a soft shear stress versus relative shear displacement curve during unloading for the interface elements is in the overprediction of the value for the effective normal stress computed below the heel of the new RCC lock wall.

Appendix A
Backfill Placement Analysis of Moist One-Dimensional Soil Column

There are two major requirements for the assignment of material parameters in the complete soil-structure interaction analysis of the new roller-compacted concrete (RCC) McAlpine Lock wall using the backfill placement method that is incorporated in SOILSTRUCT-ALPHA. One requirement is that the stress-strain model for the soil representing the backfill be representative of the soil comprising the backfill. The second requirement is that the material properties assigned to the soil used to model the backfill possess an at-rest earth pressure coefficient equal to 0.44 (from Jaky's relationship for K_o (= 1 - sin ϕ') with ϕ' equal to 34 deg). Calculations described in this appendix are used in the assignment of the value of the nominal Poisson's ratio for soil.

This appendix summarizes the results of the backfill placement analysis of the moist one-dimensional (1-D) soil column shown in Figure A1. Settlement of the soil column resulted from self-weight. Calculations are made using SOILSTRUCT-ALPHA.

Site-specific triaxial test data were unavailable for the new RCC lock wall backfill. Material parameters are assigned in the finite element analysis based on empirical correlations to the results for similar types of soils (and with the same density) for which hyperbolic stress-strain curve material parameters are available (e.g., Duncan et al. 1978[1]). The values listed in Table A1 are the result of the evaluation made for this project.

A free-field soil column is constructed to be consistent with the layering used in the Figure 6 (main text) two-dimensional finite element model for the new backfill. The compression (settlement) of the Figure A1 1-D (constrained) soil column has the following characteristics:

[1] References cited in this appendix are listed in the References at the end of the main text.

Figure A1. Finite element mesh for 1-D column analysis (0.305 m = 1 ft)

a. At any given elevation, the soil layer possess uniform compressibility.

b. The horizontal strain ϵ_x equals zero.

c. The vertical settlement at any given elevation is uniform.

$v_{nom} = $ Nominal value of Poisson's ratio

Poisson's ratio, $v = \dfrac{1}{2} \left[1 - \left[(1 - 2 \, v_{nom})(1 - R_F \, SL)^2 \right] \right]$

$P_A = $ atmospheric pressure

The backfill placement analysis of this 1-D column will serve as the model for a K_o stress-state. The computed results are used to establish that the value assigned to the nominal Poisson's ratio in the SOILSTRUCT-ALPHA analysis is consistent with K_o equal to 0.44.

Figure A1 shows the SOILSTRUCT-ALPHA finite element model of the 1-D soil column used in this appendix. The moist soil column is 55 ft (16.76 m) high. Water pressures are assumed equal to zero at the time of backfilling to elevation 425.[1] These two assumptions are consistent with the initial load cases of the backfill placement analysis of the new RCC McAlpine lock wall, described in the main body of the report. The finite element mesh for the soil column comprises 22 soil layers. They range in thickness from 1.5 ft (0.46 m) thick at the base to 5 ft (1.5 m) thick at the top of the column. The elevations of the nodes defining the soil elements in this figure were the same elevations as the nodes defining the new backfill in Figure 6 (see main text). Interface elements of approximately zero shear stiffness and very large normal stiffness are included along the vertical faces of the mesh shown in Figure A1 to take advantage of the postprocessing capability within SOILSTRUCT-ALPHA. SOILSTRUCT-ALPHA computes the horizontal and vertical resultant forces and their points of application (elevation) along specified regions of interface elements using the normal and shear stress data. The pair of 22 interface element columns delineate a single region within the backfill in this backfill placement analysis. These results expedite the calculation of the horizontal earth pressure coefficient K_h (equivalent to an at-rest coefficient K_o in the 1-D soil column) for the finite element analysis of the soil column.

Total (moist) unit weight equal to 126 pcf (2,018.32 kg/cm^3) is assigned to the soil. Material properties assigned to the hyperbolic stress-strain relationship for the soil elements are given in Table A1. The values for the parameters listed in this table are typical of dense, granular backfill. The material properties assigned to the interface elements are given in Table A2.

The backfill placement analysis of the Figure A1 soil column is conducted in 22 lifts or, equivalently, 22 load increments using SOILSTRUCT-ALPHA. The distributions of horizontal effective stress and vertical effective stress with elevation computed within the soil elements after placement of the final (22nd) lift are not shown. The shear stress τ_{xy} equals zero in all soil elements. The integral over the height of the soil column of the horizontal effective stresses σ'_x, is equal to the horizontal effective force F_x. The horizontal effective force F_x, computed by SOILSTRUCT-ALPHA using the normal effective stresses within the interface elements, equals 84,038 lb per ft of width (1,226.4 kN per m). The value of the horizontal earth pressure coefficient K_h is computed using Equation 1 in the main text.

$$K_h = \frac{F_x'}{\int_{el\ 370}^{el\ 425} \sigma'_y \, dy} \tag{1}$$

Material Region	k_n, psf/ft	k_s, psf/ft
Interface	1.0×10^8	1

Note:

Equations for Interface Model

The normal stress at the center of the interface element is given by

$\sigma_n = k_n \Delta_n$

where Δ_n is the average relative displacement normal to the interface element. The shear stress at the center of the interface element is given by

$\tau_s = k_s \Delta_s$

where Δ_s is the average relative shear displacement along the interface element.

The denominator, designated as the Effective Overburden in this report, is the integral of the vertical effective stress distribution for the 55-ft- (16.76 m) high soil column (not shown). With the Effective Overburden computed using Equation 3 (see main text) equal to 190,575 lb per ft run of wall (2,781.2 kN per m), K_h is equal to 0.44. With the lateral strain ϵ_x equal to zero along the soil column, K_h (Equation 2 in main text) is equivalent to K_o.

One of the material parameters assigned to the soil is the value for the nominal Poisson's ratio. This nominal Poisson's ratio υ_{nom} used in SOILSTRUCT-ALPHA differs from the traditional strength of materials definition of Poisson's ratio υ. The complete derivation of υ_{nom} and its corresponding value of υ is given in Appendix C of Ebeling and Pace (1997). Using the relationship

$$K_o = \frac{1 - (1 - 2\,\upsilon_{nom})\left[1 - R_F \dfrac{(1 - \sin\phi)(1 - K_o)}{2\,K_o\,\sin\phi}\right]^2}{1 + (1 - 2\,\upsilon_{nom})\left[1 - R_F \dfrac{(1 - \sin\phi)(1 - K_o)}{2\,K_o\,\sin\phi}\right]^2} \qquad (A1)$$

υ_{nom} is computed equal to 0.025 for the Table A1 material properties with K_o equal to 0.436 or 0.44. The value for K_o from the results of the SOILSTRUCT-ALPHA analysis of the soil column are consistent with the results from using Equation A1.

$$v = \frac{1 - (1 - 2\,v_{nom})*(1 - R_F\,SL)^2}{2} \qquad\qquad \text{(A2)}$$

with $R_F = 0.7$, $SL = 0.51$, and $v_{nom} = 0.025$ results in v equal to 0.30. SL is computed using SOILSTRUCT-ALPHA to be 0.51, on average, for the 22 soil elements of Figure A1.

In 1978, a bulk modulus formulation was developed by Duncan and his colleagues for use in SOILSTRUCT (Ebeling, Peters, and Clough 1992). This formulation is given in Table B1 in this report. The bulk modulus is intended to replace Poisson's ratio as the second elastic parameter. Calculation of corresponding (and equivalent) value of the bulk modulus number K_b for the bulk modulus formulation is made using Equation C10 in Appendix C of Ebeling and Pace (1997). With $K = 500$, $v_{nom} = 0.025$, and the bulk modulus exponent $m = n = 0.5$, K_b equals 175.

Appendix B
Comparison of SOILSTRUCT-ALPHA Results After Backfilling to Elevation 425 and Partial Submergence of Backfill to Elevation 395 for Two Interface Shear Stiffness Models

During postconstruction, partial submergence of the backfill to elevation (el) 395[1] (identified as load cases 25 through 38 in Table 1 (see main text)), the buoyancy forces act upward, unloading the backfill. This results in a reversal in the direction of the applied shear stress increment or, equivalently, unloading of both the new roller-compacted concrete (RCC) lock-to-backfill interface elements and the existing lock concrete-to-backfill interface elements. Interface tests reported in Peterson et al. (1976)[2] show that the interface elements follow a steeper shear-stress-versus-relative-shear-displacement curve than that described by the "primary" hyperbolic loading curve (the tangent shear stiffness $k_{st} = k_{si} [1 - R_{fi}SL_i]^2$). To model this "stiffer" behavior, the interface model parameter R_{fi} is set equal to zero for these interface elements during unloading for the results reported in the main body of the report. Figure B1a illustrates the concept behind the stiff unload interface model. This appendix compares these results with those in which the "primary" hyperbolic loading curve is followed during partial submergence of the backfill to el 395. That is, the "shear softening" is maintained during unloading (i.e., the term R_{fi} is maintained at its Table 5 (in main report) value for all interface regions). This soft unload interface model is illustrated in Figure B1b.

Figure B1. Two models for interface shear-stress-versus-relative-shear-displacement behavior

Figures B2 and B3 show the resulting effective normal and shear stress distributions along the RCC lock-to-limestone interface after backfilling to el 425 and partial submergence of the backfill to el 395 (load case 38) for the "stiff" and "soft" interface shear-stiffness-versus-relative-shear-displacement models used during unloading (load cases 25 through 38). Both effective normal and shear stress distributions are nonlinear. As anticipated, the greatest values of stress are computed below the toe of the new RCC lock (x = 0 ft (m)) because the greatest concrete mass is concentrated above this region and because of the overturning moment about the toe resulting from the 55 ft (16.76 m) of backfill. The effective normal stress below the heel of the new RCC lock (x = 47 ft (14.33 m)) is equal to 0 psf (kPa) and 307 psf (14.7 kPa) for the stiff and soft interface models used during unloading, respectively. Full base area contact is maintained in both analyses.

Table B1 summarizes the results of calculations made to determine the resultant horizontal effective force F_x and horizontal earth pressure coefficient K_h at section A-A. The resultant horizontal effective force of the Figure 14 (see main text) distribution of σ'_x, F_x, is equal to 79,102 lb per ft run of wall (1,154.4 kN per m) and acts at el 390.99 (= 0.38$H_{backfill}$) along section A-A when a stiff interface shear stiffness model is used. The corresponding value for the horizontal earth pressure coefficient K_h is 0.459 (Figure 17 in main text). The resultant horizontal effective force of the distribution of σ'_x (not shown) is made for the analysis using a soft interface shear stiffness model during unloading and F_x, is computed equal to 77,490 lb per ft run of wall (1,130.9 kN per m) and acts at el 391.15 (= 0.38$H_{backfill}$) along section A-A. The corresponding value for the horizontal earth pressure coefficient K_h is 0.45. The results from these two SOILSTRUCT-ALPHA analyses show that effect of the type of interface shear stiffness model used during partial submergence or, equivalently, unloading, of the backfill to be minor in terms of the computed values for F_x and K_h along section A-A.

Similarly, Table B1 summarizes the results of calculations made to determine the resultant vertical shear force F_v and vertical earth pressure coefficient K_v at section A-A. The resultant vertical shear force of the Figure 15 (see main text) distribution of τ_{xy}, F_v, is equal to 6,775 lb per ft run of wall (98.9 kN per m) along section A-A when a stiff interface shear stiffness model is used. The corresponding value for the vertical earth pressure coefficient K_v is 0.039 (Figure 18 in main text). The resultant vertical shear of the distribution of τ_{xy} (not shown) is made for the analysis using a soft interface shear stiffness model during unloading, and F_v is computed equal to 8,900 lb per ft run of wall (129.9 kN per m) along section A-A. The corresponding value for the horizontal earth pressure coefficient K_v is 0.052. The results from these two SOILSTRUCT-ALPHA analyses show that the effect of the type of interface shear stiffness model used during partial submergence or, equivalently, unloading, of the backfill impacts the computed values for F_v and K_v along section A-A, as anticipated. The soft interface shear stiffness model overpredicts the values of F_v and K_v for section A-A by 31 percent. This error is unconservative since F_v is a stabilizing force.
Figure B2. Effective normal stress distributions along the base of new RCC lock wall - partial submergence to el 395 (0.305 m = 1 ft, 47.88 Pa = 1 psf)

Table B2 summarizes the resultant forces and their points of application on the free body of the new RCC lock wall through which imaginary section(s) shown in Figure B4 are made. These resultant forces and their points of application are computed by SOILSTRUCT-ALPHA after backfilling to el 425 and after partial submergence of the backfill to el 395 (load case 38). The Table B2 results show that the shear force F_s along the back of the new RCC lock wall is increased by 4.9 percent with the use of the soft interface shear stiffness model during unloading (load cases 25 through 38). The downdrag force F_s is a stabilizing force, acting in the direction of the heel of the wall. More importantly, greater effective normal stresses are computed below the heel of the new RCC lock when the soft interface shear stiffness model is used during unloading (refer to Figure B2).

The values of stress level, Sl_i, computed within the interface elements change with the submergence of the backfill. During the postconstruction, partial submergence of the backfill to el 395, the buoyancy forces act upward unloading the backfill. This results in a reversal in the direction of the applied shear stress increment or, equivalently, unloading of the 22 new RCC lock-to-backfill interface elements. This is accompanied by a reduction in the effective stresses normal to the back of the lock wall within those interface elements located below the water table (el 395). At the end of backfilling to el 425 (load case 24), the average value of stress level SL_i for the interface elements equals 0.70. After partial submergence of the backfill to el 395 (load case 38), the results of the SOILSTRUCT-ALPHA interaction analysis using the stiffer inter-face model during unloading (Figure B1a) shows that the average reduction in stress level SL_i for the interface elements is 8.6 percent (ranging from zero to a 23-percent reduction). Changes in both shear and normal effective stresses during submergence account for the reduction in values of the stress levels SL_i for the 22 interface elements.

13. ABSTRACT (Maximum 200 words)

A new lock is to be constructed at the McAlpine Locks on the Ohio River at Louisville, KY. The new lock chamber will be defined by rock-founded, gravity, earth-retaining monoliths. One of the alternatives is to construct the walls using roller-compacted concrete (RCC) with a concrete facing, with the culverts located in the floor of the lock chamber.

The principal objective of this study is to assess the soil-to-structure-to-foundation interactions of a typical RCC lock wall two-dimensional section. Due to the nature of the problem, the conventional analysis techniques, which are based upon the equations of equilibrium and assumed stress distributions made along imaginary sections, did not provide sufficient information to satisfactorily evaluate the performance of this structure with regard to its interaction with the rock foundation and soil backfill. The general-purpose, nonlinear, incremental construction, finite element computer program, SOILSTRUCT-ALPHA is used to analyze the complex interactions among the lock, the backfill, and the foundation rock strata.

The analysis is accomplished in three phases. The first phase of the analysis introduces the self-weight of the existing locks and existing backfill to the shale and limestone foundation. The second phase models the incremental construction of the RCC lock wall and the incremental placement of the (moist) backfill behind the wall. The third and final phase of the soil-structure interaction analysis models the postconstruction, partial submergence of the site. The complete soil-structure-rock foundation
